Abstract

We present a Bayesian nonparametric framework for multilevel clustering which utilizes group-level context information to simultaneously discover low-dimensional structures of the group contents and partitions groups into clusters. Using the Dirichlet process as the building block, our model constructs a product base-measure with a nested structure to accommodate content and context observations at multiple levels. The proposed model possesses properties that link the nested Dirichlet processes (nDP) and the Dirichlet process mixture models (DPM) in an interesting way: integrating out all contents results in the DPM over contexts, whereas integrating out group-specific contexts results in the nDP mixture over content variables. We provide a Polya-urn view of the model and an efficient collapsed Gibbs inference procedure. Extensive experiments on real-world datasets demonstrate the advantage of utilizing context information via our model in both text and image domains.

1. Introduction

In many situations, content data naturally present themselves in groups, e.g., students are grouped into classes, classes grouped into schools, words grouped into documents, etc. Furthermore, each content group can be associated with additional context information (teachers of the class, authors of the document, time and location stamps). Dealing with grouped data, a setting known as multilevel analysis (Hox, 2010; Diez-Roux, 2000), has diverse application domains ranging from document modeling (Blei et al., 2003) to public health (Leyland & Goldstein, 2001).

This paper considers specifically the multilevel clustering problem in multilevel analysis: to jointly cluster both the content data and their groups when there is group-level context information. By context, we mean a secondary data source attached to the group of primary content data. An example is the problem of clustering documents, where each document is a group of words associated with group-level context information such as time-stamps, list of authors, etc. Another example is image clustering where visual image features (e.g. SIFT) are the content and image tags are the context.

To cluster groups together, it is often necessary to perform dimensionality reduction of the content data by forming content topics, effectively performing clustering of the content as well. For example, in document clustering, using bag-of-words directly as features is often problematic due to the large vocabulary size and the sparsity of the in-document word occurrences. Thus, a typical approach is to first apply dimensionality reduction techniques such as LDA (Blei et al., 2003) or HDP (Teh et al., 2006) to find word topics (i.e., distributions on words), then perform document clustering using the word topics and the document-level context information as features. In such a

Bayesian Nonparametric Multilevel Clustering with Group-Level Contexts

cascaded approach, the dimensionality reduction step (e.g., topic modeling) is not able to utilize the context information. This limitation suggests that a better alternative is to perform context-aware document clustering and topic modeling jointly. With a joint model, one can expect to obtain improved document clusters as well as context-guided content topics that are more predictive of the data.

Recent work has attempted to jointly capture word topics and document clusters. Parametric approaches (Xie & Xing, 2013) and require specifying the number of topics and clusters in advance. Bayesian nonparametric approaches including the nested Dirichlet process (nDP) (Rodriguez et al., 2008) and the multi-level clustering hierarchical Dirichlet Process (MLC-HDP) (Wulsin et al., 2012) can automatically adjust the number of clusters. We note that none of these methods can utilize context data.

An approach to document clustering is to employ a two-stage process. First, topic models (e.g. LDA or HDP) are applied to extract the topics and their mixture proportion for each document. Then, this is used as feature input to another clustering algorithm. Some examples of this approach include the use of LDA+Kmeans for image clustering (Elango & Jayaraman, 2005) and HDP+Affinity Propagation for clustering human activities (Nguyen et al., 2013).

A more elegant approach is to simultaneously cluster documents and discover topics. The first Bayesian nonparametric model proposed for this task is the nested Dirichlet Process (nDP) (Rodriguez et al., 2008) where documents in a cluster share the same distribution over topic atoms. Although the original nDP does not force the topic atoms to be shared across document clusters, this can be achieved by simply introducing a DP prior for the nDP base measure. The same observation was also made by (Wulsin et al., 2012) who introduced the MLC-HDP, a 3-level extension to the nDP. This model thus can cluster words, documents and document-corpora with shared topic atoms throughout the group hierarchy. Xie et al (Xie & Xing, 2013) recently introduced the Multi-Grain Clustering Topic Model which allows mixing between global topics and document-cluster topics. However, this is a parametric model which requires fixing the number of topics in advance. More crucially, all of these existing models do not attempt to utilize group-level context information.

Modelling with Dirichlet Process

We provide a brief account of the Dirichlet process and its variants. The literature on DP is vast and we refer to (Hjort et al., 2010) for a comprehensive account. Here we focus on DPM, HDP and nDP which are related to our work.

Dirichlet process (Ferguson, 1973) is a basic building block in Bayesian nonparametrics. Let \((\Theta, B, H)\) be a probability measure space, and \(\gamma\) is a positive number, a Dirichlet process DP \((\gamma, H)\) is a distribution over discrete random probability measure \(G\) on \((\Theta, B)\). Sethuraman (Sethuraman, 1994) provides an alternative constructive definition which makes the discreteness property of a draw from a Dirichlet process explicit via the stick-breaking representation: \[G = \sum_{k=1}^{\infty} \beta_k \delta_{\phi_k}\] where \(\phi_k \sim \text{H}, k = 1, \ldots, \infty\) and \(\beta = (\beta_k)_{k=1}^{\infty}\) are the weights constructed through a ‘stick-breaking’ process \(\beta_k = v_k \prod_{s<k}(1 - v_s)\) with \(v_k \sim \text{Beta}(1, \gamma)\). It can be shown that \(\sum_{k=1}^{\infty} \beta_k = 1\) with probability one, and as a convention (Pitman, 2002), we hereafter write \(\beta \sim \text{GEM}(\gamma)\).

Due to its discrete nature, Dirichlet process has been widely used in Bayesian mixture models as the prior distribution on the mixing measures, each is associated with an atom \(\phi_k\) in the stick-breaking representation of \(G\) above. A like-

2. Related Background

There have been extensive works on clustering documents in the literature. Due to limited scope of the paper, we only describe works closely related to probabilistic topic models. We note that standard topic models such as LDA (Blei et al., 2003) or its nonparametric Bayesian counter part, HDP (Teh et al., 2006) exploits the group structure for word clustering. However these models do not cluster documents.

An approach to document clustering is to employ a two-stage process. First, topic models (e.g. LDA or HDP) are applied to extract the topics and their mixture proportion for each document. Then, this is used as feature input to another clustering algorithm. Some examples of this approach include the use of LDA+Kmeans for image clustering (Elango & Jayaraman, 2005) and HDP+Affinity Propagation for clustering human activities (Nguyen et al., 2013).

A more elegant approach is to simultaneously cluster documents and discover topics. The first Bayesian nonparametric model proposed for this task is the nested Dirichlet Process (nDP) (Rodriguez et al., 2008) where documents in a cluster share the same distribution over topic atoms. Although the original nDP does not force the topic atoms to be shared across document clusters, this can be achieved by simply introducing a DP prior for the nDP base measure. The same observation was also made by (Wulsin et al., 2012) who introduced the MLC-HDP, a 3-level extension to the nDP. This model thus can cluster words, documents and document-corpora with shared topic atoms throughout the group hierarchy. Xie et al (Xie & Xing, 2013) recently introduced the Multi-Grain Clustering Topic Model which allows mixing between global topics and document-cluster topics. However, this is a parametric model which requires fixing the number of topics in advance. More crucially, all of these existing models do not attempt to utilize group-level context information.

Modelling with Dirichlet Process

We provide a brief account of the Dirichlet process and its variants. The literature on DP is vast and we refer to (Hjort et al., 2010) for a comprehensive account. Here we focus on DPM, HDP and nDP which are related to our work.

Dirichlet process (Ferguson, 1973) is a basic building block in Bayesian nonparametrics. Let \((\Theta, B, H)\) be a probability measure space, and \(\gamma\) is a positive number, a Dirichlet process DP \((\gamma, H)\) is a distribution over discrete random probability measure \(G\) on \((\Theta, B)\). Sethuraman (Sethuraman, 1994) provides an alternative constructive definition which makes the discreteness property of a draw from a Dirichlet process explicit via the stick-breaking representation: \[G = \sum_{k=1}^{\infty} \beta_k \delta_{\phi_k}\] where \(\phi_k \sim \text{H}, k = 1, \ldots, \infty\) and \(\beta = (\beta_k)_{k=1}^{\infty}\) are the weights constructed through a ‘stick-breaking’ process \(\beta_k = v_k \prod_{s<k}(1 - v_s)\) with \(v_k \sim \text{Beta}(1, \gamma)\). It can be shown that \(\sum_{k=1}^{\infty} \beta_k = 1\) with probability one, and as a convention (Pitman, 2002), we hereafter write \(\beta \sim \text{GEM}(\gamma)\).

Due to its discrete nature, Dirichlet process has been widely used in Bayesian mixture models as the prior distribution on the mixing measures, each is associated with an atom \(\phi_k\) in the stick-breaking representation of \(G\) above. A like-

2. Related Background

There have been extensive works on clustering documents in the literature. Due to limited scope of the paper, we only describe works closely related to probabilistic topic models. We note that standard topic models such as LDA (Blei et al., 2003) or its nonparametric Bayesian counter part, HDP (Teh et al., 2006) exploits the group structure for word clustering. However these models do not cluster documents.
likelihood kernel $F(\cdot)$ is used to generate data $x_i \mid \phi_k \overset{iid}{\sim} F(\cdot \mid \phi_k)$, resulting in a model known as the Dirichlet process mixture model (DPM), pioneered by the work of (Antoniak, 1974) and subsequently developed by many others. In section 3 we provide a precise definition for DPM.

While DPM models exchangeable data within a single group, the Dirichlet process can also be constructed hierarchically to provide prior distributions over multiple exchangeable groups. Under this setting, each group is modelled as a DPM and these models are ‘linked’ together to reflect the dependency among them – a formalism which is generally known as dependent Dirichlet processes (MacEachern, 1999). One particular attractive approach is the hierarchical Dirichlet processes (Teh et al., 2006) which posits the dependency among the group-level DPM by another Dirichlet process, i.e., $G_j \mid \alpha, G_0 \sim DP(\alpha, G_0)$ and $G_0 \mid \gamma, H \sim DP(\gamma, H)$ where $G_j$ is the prior for the $j$-th group, linked together via a discrete measure $G_0$ whose distribution is another DP.

Yet another way of using DP to model multiple groups is to construct random measure in a nested structure in which the DP base measure is itself another DP. This formalism is the nested Dirichlet Process (Rodriguez et al., 2008), specifically $G_j \overset{iid}{\sim} U$ where $U \sim DP(\alpha \times DP(\gamma H))$. Modeling $G_j$ (s) hierarchically as in HDP and nestedly as in nDP yields different effects. HDP focuses on exploiting statistical strength across groups via sharing atoms $\phi_k$ (s), but it does not partition groups into clusters. This statement is made precisely by noting that $P(G_j = G_{j'}) = 0$ in HDP. Whereas, nDP emphasizes on inducing clusters on both observations and distributions, hence it partitions groups into clusters. To be precise, the prior probability of two groups being clustered together is $P(G_j = G_{j'}) = \frac{1}{\alpha+1}$. Finally we note that this original definition of nDP in (Rodriguez et al., 2008) does not force the atoms to be shared across clusters of groups, but this can be achieved by simply introducing a DP prior for the nDP base measure, a modification that we use in this paper. This is made clearly in our definition for nDP mixture in section 3.

3. Multilevel Clustering with Contexts

3.1. Model description and stick-breaking

Consider data presented in a two-level group structure as follows. Denote by $J$ the number of groups; each group $j$ contains $N_j$ exchangeable data points, represented by $w_j = \{w_{j1}, w_{j2}, \ldots, w_{jN_j}\}$. For each group $j$, the group-specific context data is denoted by $x_j$. Assuming that the groups are exchangeable, the overall data is $\{(x_j, w_j)\}_{j=1}^J$. The collection $\{w_1, \ldots, w_J\}$ represents observations of the group contents, and $\{x_1, \ldots, x_J\}$ represents observations of the group-level contexts.

We now describe the generative process of MC$^2$ that generates a two-level clustering of this data. We use a group-level DP mixture to generate an infinite cluster model for groups. Each group cluster $k$ is associated with an atom having the form of a pair $(\phi_k, Q_k^*)$ where $\phi_k$ is a parameter that generates the group-level contexts within the cluster and $Q_k^*$ is a measure that generates the group contents within the same cluster.

To generate atomic pairs of context parameter and measured valued content parameter, we introduce a product base-measure of the form $H \times DP(\nu Q_0)$ for the group-level DP mixture. Drawing from a DP mixture with this base measure, each realization is a pair $(\theta_j, Q_j)$; $\theta_j$ is then used to generate the context $x_j$ and $Q_j$ is used to repeatedly produce the set of content observations $w_{j1}$ within the group $j$. Specifically,

$$ U \sim DP(\alpha(H \times DP(\nu Q_0))) \quad (\theta_j, Q_j) \overset{iid}{\sim} U \quad \text{for each group} \quad j $$

$$ x_j \sim F(\cdot \mid \theta_j), \quad \varphi_{j1} \overset{iid}{\sim} Q_j, \quad w_{j1} \sim Y(\cdot \mid \varphi_{j1}) $$

In the above, $H$ and $S$ are respectively base measures for context and content parameters $\theta_j$ and $\varphi_{j1}$. The context and content observations are then generated via the likelihood kernels $F(\cdot \mid \theta_j)$ and $Y(\cdot \mid \varphi_{j1})$. To simplify inference, $H$ and $S$ are assumed to be conjugate to $F$ and $Y$ respectively. The generative process is illustrated in Figure 1.

### Stick-breaking representation

We now derive the stick-breaking construction for MC$^2$ where all the random discrete measures are specified by a distribution over integers and a countable set of atoms. The random measure $U$ in Eq. (1) has the stick-breaking form:

$$ U = \sum_{k=1}^{\infty} \pi_k \delta(\phi_k, Q_k^*) $$

---

Figure 1. Graphical model representation for the proposed model. Right figure illustrates a stick breaking representation.
where \( \pi \sim \text{GEM}(\alpha) \) and \((\phi_k, Q^*_k) \sim H \times \text{DP}(vQ_0)\). Equivalently, this means \( \phi_k \) is drawn i.i.d. from \( H \) and \( Q^*_k \) drawn i.i.d. from \( \text{DP}(vQ_0) \). Since \( Q_0 \sim \text{DP}(\eta S) \), \( Q_0 \) and \( Q^*_k \) have the standard HDP (Teh et al., 2006) stick-breaking forms: \( Q_0 = \sum_{m=1}^{\infty} \epsilon_m \delta_{\psi_m} \) where \( \epsilon \sim \text{GEM}(\eta) \), and \( \psi_m \sim S \); \( Q^*_k = \sum_{m=1}^{\infty} \tau_{k,m} \delta_{\varphi_m} \) where \( \tau_k = (\tau_{k,1}, \tau_{k,2}, \ldots) \sim \text{DP}(v, \epsilon) \).

For each group \( j \) we sample the parameter pair \((\theta_j, Q_j) \sim \text{iid} U \); equivalently, this means drawing \( z_j \sim \pi \) and letting \( \theta_j = \varphi_j \), and \( Q_j = Q^*_j \). For the \( i \)-th content data within the group \( j \), the content parameter \( \varphi_{ji} \) is drawn \( \text{iid} \sim \psi_j \); equivalently, this means drawing \( l_{ji} \sim \tau_j \) and letting \( \varphi_{ji} = \psi_{ji} \). Figure 1 presents the graphical model of this stick-breaking representation.

### 3.2. Inference and Polya Urn View

We use collapsed Gibbs sampling, integrating out \( \phi_k(s) \), \( \psi_m(s) \), \( \pi \) and \( \tau_k(s) \). Latent variables \( z, l, \epsilon \) and the hyper-parameters \( \alpha, v, \eta \) will be resampled. We only describe the key inference steps in sampling \( z, l \) and \( \epsilon \) here and refer to the supplementary material (Nguyen et al., 2014) for the rest of the details (including how to sample the hyper-parameters).

**Sampling \( z \).** The required conditional distribution is

\[
p(z_j = k \mid z_{-j}, l, x, \alpha, H) \propto p(z_j = k, z_{-j}, x_{-j}, H) \times p(l_{ji} | z_j = k, l_{-ji}, z_{-j}, \epsilon, v)
\]

The first term can be recognized as a form of the Chinese restaurant process (CRP). The second term is the predictive likelihood for the context observations under the context \( \text{DP}(\alpha) \). The first term is in the form of a CRP similar to the one that arises during inference for HDP (Teh et al., 2006).

**Sampling \( \epsilon \).** Sampling \( \epsilon \) requires information from both \( z \) and \( l \).

\[
p(\epsilon | l, z, v, \eta) \propto p(l | \epsilon, v, z, \eta) \times p(\epsilon | \eta)
\]

(3)

Using a similar strategy in HDP, we introduce auxiliary variables \((o_{km})\), then alternatively sample together with \( \epsilon \):

\[
p(o_{km} = h | \cdot) \propto \text{Stirl}(h, n_{km}) (v\epsilon_m)^h, \ h = 0, 1, \ldots, n_{km}
\]

where \( \text{Stirl}(h, n_{km}) \) is the Stirling number of the first kind, \( n_{km} \) is the count of seeing the pair \((z_j = k, l_{ji} = m) : \forall i, j \), and finally \( M \) is the current number of active content topics. It clear that \( o_{km} \) can be sampled from a Multinomial distribution and \( \epsilon \) from an \((M + 1)\)-dim Dirichlet distribution.

**POLYA URN VIEW**

Our model exhibits a Polya-urn view using the analogy of a fleet of buses, driving customers to restaurants. Each bus represents a group and customers on the bus are data points within the group. For each bus \( j \), \( z_j \) acts as the index to the restaurant for its destination. Thus, buses form clusters at their destination restaurants according to a CRP: a new bus drives to an existing restaurant with the probability proportional to the number of other buses that have arrived at that restaurant, and with probability proportional to \( \alpha \), it goes to a completely new restaurant.

Once all the buses have delivered customers to the restaurants, all customers at the restaurants start to behave in the same manner as in a Chinese restaurant franchise (CRF) process: customers are assigned tables according to a restaurant-specific CRP; tables are assigned with dishes \( \psi_m \) (representing the content topic atoms) according to a global franchise CRP. In addition to the usual CRF, at restaurant \( k \), a single dessert \( \phi_k \) (which represents the context-generating atom, drawing \( \text{iid} \) from \( H \)) will be served to all the customers at that restaurant. Thus, every customer on the same bus \( j \) will be served the same dessert \( \varphi_{ji} \). We observe three sub-CRPs, corresponding to the three DP(s) in our model: the CRP at the dish level is due to the DP \((\eta S)\), the CRP forming tables inside each restaurant is due to the \( \text{DP}(vQ_0) \), and the CRP aggregating buses to restaurants is due to the \( \text{DP}(\alpha(H \times \text{DP}(vQ_0))) \).

### 3.3. Marginalization property

We study marginalization property for our model when either the content topics \( \varphi_{ji} \) or context topics \( \theta_j \) are
Bayesian Nonparametric Multilevel Clustering with Group-Level Contexts

marginalized out. Our main result is established in Theorem 3 where we show an interesting link to nested DP and DPM via our model.

Let $H$ be a measure over some measurable spaces $(\Theta, \Sigma)$. Let $P$ be the set of all measures over $(\Theta, \Sigma)$, suitably endowed with some $\sigma$-algebra. Let $G \sim \text{DP}(\alpha H)$ and $\theta_i \overset{iid}{\sim} G$. The collection $(\theta_i)$ then follows the DP mixture distribution which is defined formally below.

(DPM) A DPM is a probability measure over $\Theta^n \ni (\theta_1, \ldots, \theta_n)$ with the usual product sigma algebra $\Sigma^n$ such that for every collection of measurable sets $\{(S_1, \ldots, S_n) : S_i \in \Sigma, i = 1, \ldots, n\}$:

$$\text{DPM}(\theta_1 \in S_1, \ldots, \theta_n \in S_n | \alpha, H) = \int \prod_{i=1}^n G(S_i) \text{DP}(dG | \alpha H)$$

We now state a result regarding marginalization of draws from a DP mixture with a joint base measure. Consider two measurable spaces $(\Theta_1, \Sigma_1)$ and $(\Theta_2, \Sigma_2)$ and let $(\Theta, \Sigma)$ be their product space where $\Theta = \Theta_1 \times \Theta_2$ and $\Sigma = \Sigma_1 \times \Sigma_2$. Let $H^*$ be a measure over the product space $\Theta = \Theta_1 \times \Theta_2$ and let $H_1$ be the marginal of $H^*$ over $\Theta_1$ in the sense that for any measurable set $A \in \Sigma_1$, $H_1(A) = H^*(A \times \Theta_2)$. Then drawing $(\theta_1^{(1)}, \theta_1^{(2)})$ from a DP mixture with base measure $\alpha H$ and marginalizing out $(\theta_1^{(2)})$ is the same as drawing $(\theta_1^{(1)})$ from a DP mixture with base measure $H_1$. Formally

**Proposition 1.** Denote by $\theta_i$ the pair $(\theta_i^{(1)}, \theta_i^{(2)})$, there holds

$$\text{DPM}(\theta_1^{(1)} \in S_1, \ldots, \theta_n^{(1)} \in S_n | \alpha H_1) = \text{DPM}(\theta_1 \in S_1 \times \Theta_2, \ldots, \theta_n \in S_n \times \Theta_2 | \alpha H^*)$$

for every collection of measurable sets $\{(S_1, \ldots, S_n) : S_i \in \Sigma_i, i = 1, \ldots, n\}$.

**Proof.** see supplementary material (Nguyen et al., 2014).

Next we give a formal definition for the nDPM mixture:

$$\varphi_{ji} \overset{\text{id}}{\sim} Q_j, Q_j \overset{iid}{\sim} U, U \sim \text{DP}(\alpha \text{DP}(vQ_0)), Q_0 \sim \text{DP}(\eta S)$$

**Definition 2.** (nested DP Mixture) An nDPM is a probability measure over $\Theta^{\sum_{j=1}^{N_j} N_j} \ni (\varphi_{i1}, \ldots, \varphi_{iN_j}, \ldots, \varphi_{JN_j})$ equipped with the usual product sigma algebra $\Sigma^{N_1} \times \cdots \times \Sigma^{N_J}$ such that for every collection of measurable sets $\{(S_{ji}) : S_{ji} \in \Sigma, j = 1, \ldots, J, i = 1 \ldots N_j\}$:

$$\text{nDPM}(\varphi_{ji} \in S_{ji}, \forall i, j | \alpha, v, \eta, S) = \int \int \left\{ \prod_{j=1}^{N_j} \int \prod_{i=1}^{N_j} Q_j(S_{ji}) U(dQ_j) \right\} \times \text{DP}(dU | \alpha \text{DP}(vQ_0)) \text{DP}(dQ_0 | \eta, S)$$

We now have the sufficient formalism to state the marginalization result for our model.

**Theorem 3.** Given $\alpha, H$ and $\alpha, v, \eta, S$, let $\theta = (\theta_j : \forall j)$ and $\varphi = (\varphi_{ji} : \forall j, i)$ be generated as in Eq (1). Then, marginalizing out $\varphi$ results in DPM $(\theta | \alpha, H)$, whereas marginalizing out $\theta$ results in nDPM $(\varphi | \alpha, v, \eta, S)$.

**Proof.** We sketch the main steps, supplementary material (Nguyen et al., 2014) provides more detail. Let $H^* = H_1 \times H_2$, we note that when either $H_1$ or $H_2$ are random, a result similar to Proposition 1 still holds by taking the expectation on both sides of the equality. Now let $H_1 = H$ and $H_2 = \text{DP}(\nu Q_0)$ where $Q_0 \sim \text{DP}(\eta S)$ yields the proof for the marginalization of $\varphi$; let $H_1 = \text{DP}(\nu Q_0)$ and $H_2 = H$ yields the proof for the marginalization of $\theta$.

4. Experiments

We first evaluate the model via simulation studies, then demonstrate its applications on text and image modeling using three real-world datasets. Throughout this section, unless explicitly stated, discrete data is modeled by Multinomial with Dirichlet prior, while continuous data is modeled by Gaussian (unknown mean and unknown variance) with Gaussian-Gamma prior.

4.1. Simulation studies

The main goal is to investigate the posterior consistency of the model, i.e., its ability to recover the true group clusters, context distribution and content topics. To synthesize the data, we use $M = 13$ topics which are the 13 unique letters in the ICML string “INTERNATIONAL CONFERENCE MACHINE LEARNING”. Similar to (Griffiths & Steyvers, 2004), each topic $\psi_m$ is a distribution over 35 words (pixels) and visualized as a $7 \times 5$ binary image. We generate $K = 4$ clusters of 100 documents each. For each cluster, we choose a set of topics corresponding to letters in the each of 4 words in the ICML string. The topic mixing distribution $\tau_k$ is an uniform distribution over the chosen topic letters. Each cluster is also assigned a context-generating univariate Gaussian distribution. These generating parameters are shown in Figure 2 (left). Altogether we have $J = 400$ documents; for each document we sample $N_j = 50$ words and a context variable $x_j$ drawing from the cluster-specific Gaussian.

We model the word $i_{wj}$ with Multinomial and Gaussian for context $x_j$. After 100 Gibbs iterations, the number of context and content topics ($K = 4, M = 13$) are recovered correctly: the learned context atoms $\phi_k$ and topic $\psi_m$ are almost identical to the ground truth (Figure 2, right) and the model successfully identifies the 4 clusters of documents with topics corresponding to the 4 words in the
ICML string.

To demonstrate the importance of context observation, we then run LDA and HDP with only the word observations (ignoring context) where the number of topic of LDA is set to 13. As can be seen from Figure 2 (right), LDA and HDP have problems in recovering the true topics. They cannot distinguish small differences between the overlapping character topics (e.g. M vs N, or I vs T). Further analysis of the role of context in MC² is provided in supplementary material (Nguyen et al., 2014) due to lacking of space.

4.2. Experiments with Real-World Datasets

We use two standard NIPS and PNAS text datasets, and the NUS-WIDE image dataset.

NIPS contains 1,740 documents with vocabulary size 13,649 (excluding stop words); timestamps (1987-1999), authors (2,037) and title information are available and used as group-level context. PNAS contains 79,800 documents, vocab size = 36,782 with publication timestamp (915-2005). For NUS-WIDE we use a subset of the 13-class animals¹ comprising of 3,411 images (2,054 images for training and 1357 images for testing) with off-the-shelf features including 500-dim bag-of-word SIFT vector and 1000-dim bag-of-tag annotation vector.

Text Modeling with Document-Level Contexts

We use NIPS and PNAS datasets with 90% for training and 10% for held-out perplexity evaluation. We compare the perplexity with HDP (Teh et al., 2006) where no group-level context can be used, and npTOT (Dubey et al., 2012) where only timestamp information can be used. We note that unlike our model, npTOT requires replication of document timestamp for every word in the document, which is somewhat unnatural.

We use perplexity score (Blei et al., 2003) on held-out data as performance metric, defined as

\[
\text{exp}\left\{-\sum_{j=1}^{J} \log p\left(\mathbf{w}_{j}^{\text{test}} | \mathbf{z}_{\text{train}}, \mathbf{w}_{\text{train}}\right) / \left(\sum_{j} \mathbf{N}_{j}^{\text{test}}\right)\right\}
\]

To ensure fairness and comparable evaluation, only words in held-out data is used to compute the perplexity. We use univariate Gaussian for timestamp and Multinomial distributions for words, tags and authors. We ran collapsed Gibbs for 500 iterations after 100 burn-in samples.

Table 1 shows the results where MC² achieves significant better performance. This shows that group-level context information during training provide useful guidance for the modelling tasks. Regarding the informative aspect of group-level context, we achieve better perplexity with timestamp information than with titles and authors. This may be explained by the fact that 1361 authors (among 2037) show up only once in the data while title provides little additional information than what already in that abstracts. Interestingly, without the group-level context information, our model still predicts the held-out words better than HDP. This suggests that inducing partitions over documents simultaneously with topic modelling is beneficial.

Beyond the capacity of HDP and npTOT, our model can induce clusters over documents (value of K in Table 1). Figure 3 shows an example of one such document cluster discovered from NIPS data with authors as context.

Our proposed model also allows flexibility in deriving useful understanding into the data and to evaluate on its predictive capacity (e.g., who most likely wrote this article, which authors work in the same research topic and so on). Another possible usage is to obtain conditional distributions.

Table 1. Perplexity evaluation on PNAS and NIPS datasets. (K,M) is (#cluster,#topic). (Note: missing results are due to title and author information not available in PNAS dataset).

Our result coincides with results independently searched from Google Scholar using the top 50 hits.

First we perform the perplexity evaluation for this dataset using a similar setting as in the previous section. Table 2 presents the results where our model again outperforms HDP even when no context (tags) is used for training.

Next we evaluate the clustering quality of the model using the provided 13 classes as ground truth. We report performance on four well-known clustering evaluation metrics: Purity, Normalized Mutual Information (NMI), Rand-Index (RI), and Fscore (detailed in (Rand, 1971; Cai et al., 2011)). We use the following baselines for comparison:

- Kmeans and Non-negative Matrix Factorization (NMF) (Lee & Seung, 1999). For these methods, we need to specify the number of clusters in advance, hence we vary this number from 10 to 40. We then

Bayesian Nonparametric Multilevel Clustering with Group-Level Contexts

Missing and unlabelled data is commonly encountered in practical applications. Here we examine the effect of context observability on document clustering performance. To do so, we again use the NUS-WIDE 13-animal subset as described previously, then vary the amount of observing context observation $x_j$ with missing proportion ranges from 0% to 100%.

Table 3. Clustering performance with different missing proportion of context observation $x_j$.

Table 3 reports the result. We make two observations: a) utilizing context results in a big performance gain as evidenced in the difference between the top and bottom row of the table, and b) as the proportion of missing context starts to increase, the performance degrades gracefully up to 50% missing. This demonstrates the robustness of model against the possibility of missing context data.

5. Conclusion

We have introduced an approach for multilevel clustering when there are group-level context information. Our MC$^2$ provides a single joint model for utilizing group-level contexts to form group clusters while discovering the shared topics of the group contents at the same time. We provide a collapsed Gibbs sampling procedure and perform extensive experiments on three real-world datasets in both text and image domains. The experimental results using our model demonstrate the importance of utilizing context information in clustering both at the content and at the group level. Since similar types of contexts (time, tags, locations, ages, genres) are commonly encountered in many real-world data sources, we expect that our model will also be further applicable in other domains.

Our model contains a novel ingredient in DP-based Bayesian nonparametric modeling: we propose to use a base measure in the form of a product between a context-generating prior $H$ and a content-generating prior $DP(vQ_0)$. Doing this results in a new model with one marginal being the DPM and another marginal being the nDP mixture, thus establishing an interesting bridge between the DPM and the nDP. Our product base measure construction can be generalized to yield new models suitable for data presenting in more complicated nested group structures (e.g., more than 2-level deep).
